## Package 'BFI'

January 20, 2025

```
Type Package
Title Bayesian Federated Inference
Version 2.0.1
Date/Publication 2024-07-04 07:10:10 UTC
Author Hassan Pazira [aut, cre] (<a href="https://orcid.org/0000-0002-4266-6877">https://orcid.org/0000-0002-4266-6877</a>),
      Emanuele Massa [aut] (<a href="https://orcid.org/0000-0001-5715-2572">https://orcid.org/0000-0001-5715-2572</a>),
      Marianne A. Jonker [aut] (<a href="https://orcid.org/0000-0003-0134-8482">https://orcid.org/0000-0003-0134-8482</a>)
Maintainer Hassan Pazira <a href="hassan.pazira@radboudumc.nl">hassan.pazira@radboudumc.nl</a>
Description The Bayesian Federated Inference ('BFI') method combines inference results ob-
      tained from local data sets in the separate centers. In this version of the pack-
      age, the 'BFI' methodology is programmed for linear, logistic and survival regression mod-
      els. For GLMs, see Jonker, Pazira and Coolen (2024) <doi:10.1002/sim.10072>; for sur-
      vival models, see Pazira, Massa, Wei-
      jers, Coolen and Jonker (2024) <doi:10.48550/arXiv.2404.17464>; and for heterogeneous popu-
      lations, see Jonker, Pazira and Coolen (2024) <doi:10.48550/arXiv.2402.02898>.

	b.diag			3
	BFI-package			

## Description

The Bayesian Federated Inference method combines inference results from different (medical) centers without sharing the data. In this version of the package, the user can fit models specifying Gaussian, Binomial (Logistic) and Survival families.

## **Details**

Package: BFI
Type: Package
Version: 2.0.1
Date/Publication: 2024-04-27
License: GPL (>=2)

MAP. estimation and bfi are the main functions. All other functions are utility functions.

Some examples are provided in the vignettes accompanying this package in order to show how the package can be applied to real data. The vignettes can be found on the package website at <a href="https://hassanpazira.github.io/BFI/">https://hassanpazira.github.io/BFI/</a> or within R once the package has been installed, e.g., via vignette("BFI", package = "BFI").

b.diag

Create a Block Diagonal Matrix

#### **Description**

Construct a block diagonal matrix using multiple given block matrices.

#### Usage

```
b.diag(..., fill = 0)
```

## **Arguments**

individual matrices or one list of matrices.non-block-diagonal elements. Default is 0.

#### **Details**

Avoid combining matrices and lists for the . . . argument.

b.diag() covers the arguments of type "character".

If a *sparse* matrix needed, run the following:

library(Matrix); Matrix(b\_diag, sparse = TRUE)

where b\_diag is the matrix returned by b.diag().

#### Value

b.diag() returns a block diagonal matrix obtained by combining the arguments.

#### Author(s)

Hassan Pazira

Maintainer: Hassan Pazira < hassan.pazira@radboudumc.nl>

#### **Examples**

```
b.diag(1, matrix(1:3, 3,4), diag(3:2))
b.diag(matrix(1:6, 2), as.character(2))
lists <- list(1, 2:3, diag(4:6), 7, cbind(8,9:12), 13:15)
b.diag(lists)
identical(b.diag(lists), b.diag(lapply(lists, as.matrix)))
b.diag(replicate(3, matrix(round(rnorm(9)), 3, 3), simplify=FALSE))</pre>
```

bfi

Bayesian Federated Inference

## Description

bfi function can be used (on the central server) to combine inference results from separate datasets (without combining the data) to approximate what would have been inferred had the datasets been merged. This function can handle linear, logistic and survival regression models.

#### Usage

```
bfi(theta_hats = NULL,
    A_hats,
    Lambda,
    family = c("gaussian", "binomial", "survival"),
    stratified = FALSE,
    strat_par = NULL,
    center_spec = NULL,
    basehaz = c("weibul", "exp", "gomp", "poly", "pwexp"),
    theta_A_polys = NULL,
    q_ls,
    center_zero_sample = FALSE,
    which_cent_zeros,
    zero_sample_covs,
    refer_cats,
    zero_cats,
    lev_no_ref_zeros)
```

#### **Arguments**

theta\_hats

a list of L vectors of the maximum a posteriori (MAP) estimates of the model parameters in the L centers. These vectors must have equal dimensions. See

'Details'.

A\_hats

a list of L minus curvature matrices for L centers. These matrices must have equal dimensions. See 'Details'.

family

a character string representing the family name used for the local centers. Can be abbreviated.

Lambda

a list of L+1 matrices. The k matrix is the chosen inverse variance-covariance matrix of the Gaussian distribution that is used as prior distribution in center k, where  $k=1,2,\ldots,L$ . The last matrix is the chosen variance-covariance matrix for the Gaussian prior of the (fictive) combined data set. If stratified = FALSE, all L+1 matrices must have equal dimensions. While, if stratified = TRUE, the first L matrices must have equal dimensions and the last matrix should have a different (greater) dimention than the others. See 'Details'.

stratified

logical flag for performing the stratified analysis. If stratified = TRUE, the parameter(s) selected in the strat\_par argument are allowed to be different across centers, except when the argument center\_spec is not NULL. Default is stratified = FALSE. See 'Details' and 'Examples'.

strat\_par

a one- or two-element integer vector for indicating the stratification parameter(s). The values 1 and/or 2 are/is used to indicate that the "intercept" and/or "sigma2" are allowed to vary, respectively. This argument is used only when stratified = TRUE and center\_spec = NULL. Default is  $strat_par = NULL$ , but if stratified = TRUE,  $strat_par$  can not be NULL unless there is a center specific variable. For the binomial family the length of the vector should be at most one which refers to "intercept", and the value of this element should be 1. For gaussian family this vector can be 1 for indicating the "intercept" only, 2 for indicating the "sigma2" only, and c(1, 2) for both "intercept" and "sigma2". See 'Details' and 'Examples'.

center\_spec

a vector of L elements for representing the center specific variable. This argument is used only when stratified = TRUE and strat\_par = NULL. Each element represents a specific feature of the corresponding center. There must be only one specific value or attribute for each center. This vector could be a numeric, characteristic or factor vector. Note that, the order of the centers in the vector center\_spec must be the same as in the list of the argument theta\_hats. The used data type in the argument center\_spec must be categorical. Default is center\_spec = NULL. See also 'Details' and 'Examples'.

basehaz

a character string representing one of the available baseline hazard functions; exponential ("exp"), Weibull ("weibul", the default), Gompertz ("gomp"), exponentiated polynomial ("poly"), and piecewise exponential ("pwexp"). It is only used when family = "survival". Can be abbreviated.

theta\_A\_polys

a list with L elements so that each element is the array theta\_A\_ploy (the output of the MAP.estimation function, MAP.estimation()\$theta\_A\_ploy) for the corresponding center. This argument, theta\_A\_polys, is only used if family = "survival" and basehaz = "poly". See 'Details'.

 $q_ls$ 

a vector with L elements in which each element is the order (minus 1) of the exponentiated polynomial baseline hazard function for the corresponding center, i.e., each element is the value of  $q_1$  (the output of the MAP.estimation function, MAP.estimation() $q_1$ . This argument,  $q_1$ s, is only used if family = "survival" and basehaz = "poly". It can also be a scalar which represents the maximum value of the  $q_1$ 's across the centers.

center\_zero\_sample

logical flag indicating whether the center has a categorical covariate with no observations/individuals in one of the categories. Default is center\_zero\_sample = FALSE. For more detailes see 'References'.

which\_cent\_zeros

an integer vector representing the center(s) which has one categorical covariate with no individuals in one of the categories. It is used if center\_zero\_sample = TRUE.

zero\_sample\_covs

a vector in which each element is a character string representing the categorical covariate that has no samples/observations in one of its categories for the corresponding center. Each element of the vector can be obtained from the output of the MAP.estimation function for the corresponding center, MAP.estimation()\$zero\_sample\_cov. It is used when center\_zero\_sample = TRUE.

refer\_cats

a vector in which each element is a character string representing the reference category for the corresponding center. Each element of the vector can be obtained from the output of the MAP.estimation function for the corresponding center, MAP.estimation()\$refer\_cat. This vector is used when center\_zero\_sample = TRUE.

zero\_cats

a vector in which each element is a character string representing the category with no samples/observations for the corresponding center. Each element of the vector can be obtained from the output of the MAP.estimation function for the corresponding center, i.e., MAP.estimation()\$zero\_cat. It is used when center\_zero\_sample = TRUE.

lev\_no\_ref\_zeros

a list in which the number of elements equals the length of the which\_cent\_zeros argument. Each element of the list is a vector containing the names of the levels of the categorical covariate that has no samples/observations in one of its categories for the corresponding center. However, the name of the category with no samples and the name of the reference category are excluded from this vector. Each element of the list can be obtained from the output of the MAP.estimation function, i.e., MAP.estimation()\$lev\_no\_ref\_zero. This argument is used if center\_zero\_sample = TRUE.

## Details

bf i function implements the BFI approach described in the papers Jonker et. al. (2024a), Pazira et. al. (2024) and Jonker et. al. (2024b) given in the references. The inference results gathered from different (L) centers are combined, and the BFI estimates of the model parameters and curvature matrix evaluated at that point are returned.

The inference result from each center must be obtained using the MAP.estimation function separately, and then all of these results (coming from different centers) should be compiled into a list to be used as an input of bfi(). The models in the different centers should be defined in exactly the same way; among others, exactly the same covariates should be included in the models. The parameter vectors should be defined exactly the same, so that the L vectors and matrices in the input lists theta\_hat's and A\_hat's are defined in the same way (e.g., the covariates need to be included in the models in the same order).

Note that the order of the elements in the lists theta\_hats, A\_hats and Lambda, must be the same with respect to the centers, so that in every list the element at the  $\ell$  position is from the center  $\ell$ . This should also be the case for the vector center\_spec.

If for the locations intercept = FALSE, the stratified analysis is not possible anymore for the binomial family.

If stratified = FALSE, both strat\_par and center\_spec must be NULL (the defaults), while if stratified = TRUE only one of the two must be NULL.

If stratified = FALSE and all the L+1 matrices in Lambda are equal, it is sufficient to give a (list of) one matrix only. In both cases of the stratified argument (TRUE or FALSE), if only the first L matrices are equal, the argument Lambda can be a list of two matrices, so that the fist matrix represents the chosen variance-covariance matrix for local centers and the second one is the chosen matrix for the combined data set. The last matrix of the list in the argument Lambda can be built by the function inv.prior.cov().

If the data type used in the argument center\_spec is continuous, one can use stratified = TRUE and center\_spec = NULL, and set strat\_par not to NULL (i.e., to 1, 2 or both (1, 2)). Indeed, in this case, the stratification parameter(s) given in the argument strat\_par are assumed to be different across the centers.

When family = 'survival' and basehaz = 'poly', the arguments theta\_hats and A\_hats should not be provided. Instead, the theta\_A\_polys and q\_ls arguments should be defined using the local information, specifically MAP.estimation()\$theta\_A\_poly and MAP.estimation()\$q\_l, respectively. See the last example in 'Examples'.

#### Value

bfi returns a list containing the following components:

the ta\_hat the vector of estimates obtained by combining the inference results from the L

centers with the 'BFI' methodology. If an intercept was fitted in every center and stratified = FALSE, there is only one general "intercept" in this vector, while if stratified = TRUE and strat\_par = 1, there are L different intercepts

in the model, for each center one;

A\_hat minus the curvature (or Hessian) matrix obtained by the 'BFI' method for the

combined model. If stratified = TRUE, the dimension of the matrix is always

greater than when stratified = FALSE;

sd the vector of standard deviation of the estimates in theta\_hat obtained from

the matrix in A\_hat, i.e., the vector equals sqrt(diag(solve(A\_hat))) which equals the square root of the elements at the diagonal of the inverse of the A\_hat

matrix.

family the family object used;

basehaz the baseline hazard function used;

stratified whether a stratified analysis was done or not.;

hazards.fun 13

hazards.fun

Compute the estimated (baseline/cumulative) hazard and (baseline) survival functions

## Description

For a given vector of times, hazards.fun computes the estimated baseline hazard, cumulative baseline hazard, hazard, baseline survival, and survival functions. It can be used for prediction on a new sample.

#### Usage

```
hazards.fun(time,
    z = NULL,
    p,
    theta_hat,
    basehaz = c("weibul", "exp", "gomp", "poly", "pwexp"),
    q_max,
    timax)
```

#### **Arguments**

time	the vector containing the time values for which the hazard rate is computed. If the argument z is not NULL, then the length of the argument time should be the number of columns of z, which is $p$ .
Z	a new observation vector of length $p$ . If $z = NULL$ (the default), then the relative risk $(z^{\top}\beta)$ is considered a vector of 1 with length $n$ .
p	the number of coefficients. It is taken equal to the number of elements of the argument z, if z is not NULL.

14 hazards.fun

theta\_hat a vector contains the values of the estimated parameters. The first p values

represent the coefficient parameters  $(\beta)$ , while the remaining values pertain to

the parameters of the baseline hazard function  $(\omega)$ .

basehaz a character string representing one of the available baseline hazard functions;

exponential ("exp"), Weibull ("weibul", the default), Gompertz ("gomp"), exponentiated polynomial ("poly"), and piecewise exponential ("pwexp").

Can be abbreviated.

q\_max a value represents the order of the exponentiated polynomial baseline hazard

function. This argument should only be used when basehaz = "poly". In the case of multiple centers, the maximum value of the orders should be used.

ql.LRT() can be used for obtaining of the order of each center.

timax a value represents the minimum (or maximum) value of the maximum times

observed in the different centers. This argument should only be used when

basehaz = "pwexp".

#### **Details**

hazards. fun computes the estimated baseline hazard, cumulative baseline hazard, hazard, baseline survival, and survival functions at different time points specified in the argument time.

The function hazards.fun() can be used for prediction purposes with new sample. The arguments time and z should be provided for the new data.

#### Value

hazards. fun returns a list containing the following components:

bhazard the vector of estimates of the baseline hazard function at the time points given

by the argument time;

cbhazard the vector of estimates of the cumulative baseline hazard function at the time

points specified in the argument time;

bsurvival the vector of estimates of the baseline survival function at the time points given

by the argument time;

hazard the vector of estimates of the hazard function at the time points given by the

argument time;

chazard the vector of estimates of the cumulative hazard function at the time points spec-

ified in the argument time;

survival the vector of estimates of the survival function at the time points given by the

argument time.

inv.prior.cov

Creates an inverse covariance matrix for a Gaussian prior

#### **Description**

inv.prior.cov constructs a diagonal inverse covariance matrix for the Gaussian prior distribution based on the design matrix of covariates. This construction accounts for the number of regression parameters, especially when dealing with categorical covariates. For a linear model, it also includes an additional row and column to represent the variance of the measurement error. In the case of a survival model, it considers the parameters of the baseline hazard function as well.

#### **Usage**

## **Arguments**

Χ

design matrix of dimension  $n \times p$ , where n is the number of samples observed, and p is the number of predictors/variables so excluding the intercept.

lambda

the vector used as the diagonal of the (inverse covariance) matrix that will be created by inv.prior.cov(). The length of the vector depends on the number of columns of X, type of the covariates (continuous/dichotomous or categorical), family, whether an intercept is included in the model, and whether stratified analysis is desired. When stratified = FALSE, lambda could be

a single positive number (if all values in the vector are equal), a vector of two elements (the first is used for regression parameters including "intercept" and the second for the "sigma2" in the gaussian family or for the baseline hazard parameters in the survival case), or a vector of length equal to the number of model parameters. However, the length of lambda is different when stratified = TRUE, see 'Details' for more information. Default is lambda = 1.

L

the number of centers. This argument is used only when stratified = TRUE. Default is L = 2. See 'Details' and 'Examples'.

family

a description of the error distribution. This is a character string naming a family of the model. In the current version of the package, the family of model can be "gaussian" (with identity link function), "binomial" (with logit link function), or "survival". Can be abbreviated. By default the gaussian family is used. In case of a linear regression model, family = "gaussian", there is an extra model parameter for the variance of measurement error. While in the case of survival model, family = "survival", the number of the model parameters depend on the choice of baseline hazard functions, see 'Details' for more information.

intercept

logical flag for having an intercept. It does not used when family = "survival". By changing the intercept the dimension of the inverse covariance matrix changes. If intercept = TRUE (the default), the output matrix created by inv.prior.cov() has one row and one column related to intercept, while if intercept = FALSE, the resulting matrix does not have the row and column called intercept.

stratified

logical flag for performing the stratified analysis. If stratified = TRUE, the parameter(s) selected in the strat\_par argument are allowed to be different across centers. This argument should only be used when designing the inverse covariance matrix for the (fictive) combined data, i.e., the last matrix for the Lambda argument in bfi(). If inv.prior.cov() is used for the analysis in the local centers (to built the L first matrices for the Lambda argument in bfi()), this argument should be FALSE, even if the BFI analysis is stratified. It does not used when family = "survival". Default is stratified = FALSE. See 'Details' and 'Examples'.

strat\_par

a one- or two-element integer vector for indicating the stratification parameter(s). The values 1 and/or 2 are/is used to indicate that the "intercept" and/or "sigma2" are allowed to vary, respectively. This argument is used only when stratified = TRUE. Default is  $strat_par = NULL$ , but if stratified = TRUE,  $strat_par$  can not be NULL. For the binomial family the length of the vector should be one which refers to "intercept", and the value of this element should be 1. For gaussian this vector can be 1 for indicating the "intercept" only, 2 for indicating the "sigma2" only, and c(1, 2) for both "intercept" and "sigma2". See 'Examples'.

center\_spec

a vector of L elements for representing the center specific variable. This argument is used only when stratified = TRUE and strat\_par = NULL. Each element represents a specific feature of the corresponding center. There must be only one specific value or attribute for each center. This vector could be a numeric, characteristic or factor vector. Note that, the order of the centers in the vector center\_spec must be the same as in the list of the argument theta\_hats

in the function bfi(). The used data type in the argument center\_spec must be categorical. Default is center\_spec = NULL. See also 'Details' and 'Examples'.

basehaz a character string representing one of the available baseline hazard functions;

exponential ("exp"), Weibull ("weibul", the default), Gompertz ("gomp"), exponentiated polynomial ("poly"), and piecewise constant exponential ("pwexp"). Can be abbreviated. It is only used when family = "survival".

max\_order an integer representing the maximum value of q\_1, which is the order/degree

minus 1 of the exponentiated polynomial baseline hazard function. This argument is only used when family = "survival" and basehaz = "poly". Default

is 2.

n\_intervals an integer representing the number of intervals in the piecewise exponential

baseline hazard function. This argument is only used when family = "survival"

and basehaz = "pwexp". Default is 4.

#### **Details**

inv.prior.cov creates a diagonal matrix with the vector lambda as its diagonal. The argument stratified = TRUE should only be used to construct a matrix for the prior density in case of stratification in the fictive combined data. Never be used for the construction of the matrix for analysis in the centers.

When stratified = FALSE, the length of the vector lambda depends on the covariate matrix X, family, basehaz, and whether an "intercept" is included in the model. For example, if the design matrix X has p columns with continuous or dichotomous covariates, family = gaussian, and intercept = TRUE, then lambda should have p+2 elements. In this case, if in X there is a categorical covariate with q>2 categories, then the length of lambda increases with q-2.

All values of lambda should be non-negative as they represent the inverse of the variance of the Gaussian prior. This argument is considered as the inverse of the variance of the prior distribution for:  $(\beta_0, \beta)$  if family = "binomial" and intercept = TRUE;  $(\beta_0, \beta, \sigma^2)$  if family = "gaussian" and intercept = TRUE; and  $(\beta, \omega)$  if family = "survival".

If all values in the vector lambda equal, one value is enough to be given as entry. If lambda is a scalar, the function inv.prior.cov sets each value at the diagonal equal to lambda. When lambda is two dimensional: if family = "binomial", the first and second values are used for the inverse of the variance of the prior distribution for the intercept ( $\beta_0$ ) and regression parameters ( $\beta$ ), respectively; If family = "gaussian", the first and second values are used for the inverse of the variance of the prior distribution for the regression parameters including the intercept ( $\beta_0$ ,  $\beta$ ) and variance of the measurement error ( $\sigma^2$ ), respectively; If family = "survival", the first and second values are used for the inverse of the variance of the prior distribution for the regression parameters ( $\beta$ ) and baseline hazard parameters ( $\omega$ ), respectively.

If stratified = TRUE the length of the vector lambda should be equal to the number of parameters in the combined model.

If intercept = FALSE, for the binomial family the stratified analysis is not possible therefore stratified can not be TRUE.

If stratified = FALSE, both strat\_par and center\_spec must be NULL (the defaults), while if stratified = TRUE only one of the two must be NULL.

The output of inv.prior.cov() can be used in the main functions MAP.estimation() and bfi().

#### Value

inv.prior.cov returns a diagonal matrix. The dimension of the matrix depends on the number of columns of X, type of the covariates (continuous/dichotomous or categorical), intercept, family, and basehaz.

```

#### **Description**

MAP. estimation function is used (in local centers) to compute Maximum A Posterior (MAP) estimators of the parameters for Generalized Linear Models (GLM) and Survival models.

#### Usage

#### **Arguments**

У

response vector. If the "binomial" family is used, this argument is a vector with entries 0 (failure) or 1 (success). Alternatively, for this family, the response can be a matrix where the first column is the number of "successes" and the second column is the number of "failures". For the "survival" family, the response is a matrix where the first column is the survival time, named "time", and the second column is the censoring indicator, named "status", with 0 indicating censoring time and 1 indicating event time.

Χ

design matrix of dimension  $n \times p$ , where p is the number of covariates or predictors. Note that the order of the covariates must be the same across the centers; otherwise, the output estimates of bfi() will be incorrect.

family

a description of the error distribution. This is a character string naming a family of the model. In the current version of the package, the family of model can be "gaussian" (with identity link function), "binomial" (with logit link function), or "survival". Can be abbreviated. By default the gaussian family is used. In case of a linear regression model, family = "gaussian", there is an extra model parameter for the variance of measurement error. While in the case of survival model, family = "survival", the number of the model parameters depend on the choice of baseline hazard functions, see 'Details' for more information.

Lambda

the inverse variance-covariance matrix of the Gaussian distribution that is used as prior distribution for the model parameters. The dimension of the matrix depends on the number of columns of X, type of the covariates (continuous /

dichotomous or categorical), family, and whether an intercept is included (if applicable). However, Lambda can be easily created by inv.prior.cov(). See inv.prior.cov for more information.

intercept

logical flag for fitting an intercept. If intercept=TRUE (the default), the intercept is fitted, i.e., it is included in the model, and if intercept=FALSE it is set to zero, i.e., it's not in the model. This argument is not used if family = "survival".

initial

a vector specifying initial values for the parameters to be optimized over. The length of initial is equal to the number of model parameters and thus, is equal to the number of rows or columns of Lambda. Since the 'L-BFGS-B' method is used in the algorithm, these values should always be finite. Default is a vector of zeros, except for the survival family with the poly function, where it is a vector with the first p elements as zeros for coefficients ( $\beta$ ) and -0.5 for the remaining parameters ( $\omega$ ). For the gaussian family, the last element of the initial vector could also be considered negative, because the Gaussian prior was applied to  $log(\sigma^2)$ .

basehaz

a character string representing one of the available baseline hazard functions; exponential ("exp"), Weibull ("weibul", the default), Gompertz ("gomp"), exponentiated polynomial ("poly"), and piecewise constant exponential ("pwexp"). Can be abbreviated. It is only used when family = "survival". If local sample size is large and the shape of the baseline hazard function is completely unknown, the "exponentiated polynomial" and "piecewise exponential" hazard functions would be preferred above the lower dimensional alternatives. However, if the local samples size is low, one should be careful using the "piecewise exponential" hazard function with many intervals.

alpha

a significance level used in the chi-squared distribution (with one degree of freedom and  $1-\alpha$  representing the upper quantile) to conduct a likelihood ratio test for obtaining the order of the exponentiated polynomial baseline hazard function. It is only used when family = "survival" and basehaz = "poly". Default is 0.1. See 'Details'.

max\_order

an integer representing the maximum value of  $q_1$ , which is the order/degree minus 1 of the exponentiated polynomial baseline hazard function. This argument is only used when family = "survival" and basehaz = "poly". Default is 2.

n\_intervals

an integer representing the number of intervals in the piecewise exponential baseline hazard function. This argument is only used when family = "survival" and basehaz = "pwexp". Default is 4.

min\_max\_times

a scalar representing the minimum of the maximum event times observed in the centers. The value of this argument should be defined by the central server (which has access to the maximum event times of all the centers) and is only used when family = "survival" and basehaz = "pwexp".

center\_zero\_sample

logical flag indicating whether the center has a categorical covariate with no observations/individuals in one of the categories. Default is center\_zero\_sample = FALSE.

zero\_sample\_cov

either a character string or an integer representing the categorical covariate that has no samples/observations in one of its categories. This covariate should have at least two categories, one of which is the reference. It is used when

center\_zero\_sample = TRUE.

refer\_cat a character string representing the reference category. The category with no

observations (the argument zero\_cat) cannot be used as the reference in the

argument refer\_cat. It is used when center\_zero\_sample = TRUE.

zero\_cat a character string representing the category with no samples/observations. It is

used when center\_zero\_sample = TRUE.

control a list of control parameters. See 'Details'.

#### **Details**

MAP. estimation function finds the Maximum A Posteriori (MAP) estimates of the model parameters by maximizing the log-posterior density with respect to the parameters, i.e., the estimates equal the values for which the log-posterior density is maximal (the posterior mode). In other words, MAP.estimation() optimizes the log-posterior density with respect to the parameter vector to obtain its MAP estimates. In addition to the model parameters (i.e., coefficients ( $\beta$ ) and variance error ( $\sigma_e^2$ ) for gaussian or the parameters of the baseline hazard ( $\omega$ ) for survival), the curvature matrix (Hessian of the log-posterior) is estimated around the mode.

The MAP.estimation function returns an object of class 'bfi'. Therefore, summary() can be used for the object returned by MAP.estimation().

For the case where family = "survival" and basehaz = "poly", we assume that in all centers the  $q_\ell$ 's are equal. However, the order of the estimated polynomials may vary across the centers so that each center can have different number of parameters, say  $q_\ell+1$ . After obtaining the estimates within the local centers (by using MAP . estimation()) and having all estimates in the central server, we choose the order of the polynomial approximation for the combined data to be the maximum of the orders of the local polynomial functions, i.e.,  $\max\{q_1,\ldots,q_L\}$ , to approximate the global baseline hazard (exponentiated polynomial) function more accurately. This is because the higher-order polynomial approximation can capture more complex features and details in the combined data. Using the higher-order approximation ensures that we account for the higher-order moments and features present in the data while maintaining accuracy. As a result, all potential cases are stored in the theta\_A\_poly argument to be used in bfi() by the central server. For further information on the survival family, refer to the 'References' section.

To solve unconstrained and bound-constrained optimization problems, the MAP.estimation function utilizes an optimization algorithm called Limited-memory Broyden-Fletcher-Goldfarb-Shanno with Bound Constraints (L-BFGS-B), Byrd et. al. (1995). The L-BFGS-B algorithm is a limited-memory "quasi-Newton" method that iteratively updates the parameter estimates by approximating the inverse Hessian matrix using gradient information from the history of previous iterations. This approach allows the algorithm to approximate the curvature of the posterior distribution and efficiently search for the optimal solution, which makes it computationally efficient for problems with a large number of variables.

By default, the algorithm uses a relative change in the objective function as the convergence criterion. When the change in the objective function between iterations falls below a certain threshold ('factr') the algorithm is considered to have converged. The convergence can be checked with the argument convergence in the output. See 'Value'.

In case of convergence issue, it may be necessary to investigate and adjust optimization parameters to facilitate convergence. It can be done using the initial and control arguments. By the argument initial the initial points of the interative optimization algorithm can be changed, and the argument control is a list that can supply any of the following components:

maxit: is the maximum number of iterations. Default is 150;

factr: controls the convergence of the 'L-BFGS-B' method. Convergence occurs when the reduction in the objective is within this factor of the machine tolerance. Default for factr is 1e7, which gives a tolerance of about 1e-9. The exact tolerance can be checked by multiplying this value by .Machine\$double.eps;

pgtol: helps to control the convergence of the 'L-BFGS-B' method. It is a tolerance on the projected gradient in the current search direction, i.e., the iteration will stop when the maximum component of the projected gradient is less than or equal to pgtol, where pgtol  $\geq 0$ . Default is zero, when the check is suppressed;

trace: is a non-negative integer. If positive, tracing information on the progress of the optimization is produced. Higher values may produce more tracing information: for the method 'L-BFGS-B' there are six levels of tracing. To understand exactly what these do see the source code of optim function in the **stats** package;

REPORT: is the frequency of reports for the 'L-BFGS-B' method if 'control\$trace' is positive. Default is every 10 iterations;

1mm: is an integer giving the number of BFGS updates retained in the 'L-BFGS-B' method. Default is 5.

#### Value

MAP. estimation returns a list containing the following components:

theta_hat	the vector corresponding to the maximum a posteriori (MAP) estimates of the parameters. For the gaussian family, the last element of this vector is $\sigma^2$ ;
A_hat	minus the curvature (or Hessian) matrix around the point theta_hat. The dimension of the matrix is the same as the argument Lambda;
sd	the vector of standard deviation of the MAP estimates in theta_hat, that is $\ensuremath{sqrt}(\ensuremath{diag}(\ensuremath{solve}(\ensuremath{A}_{-}\ensuremath{hat}));$
Lambda	the inverse variance-covariance matrix of the Gaussian distribution that is used as prior distribution for the parameters. It's exactly the same as the argument Lambda;
formula	the formula applied;
names	the names of the model parameters;
n	sample size;
np	the number of coefficients;
q_1	the order/degree minus 1 of the exponentiated polynomial baseline hazard function determined for the current center by the likelihood ratio test. This output argument, q_1, is only shown when family = "survival" and basehaz = "poly", and will be used in the function bfi();

theta\_A\_poly an array where the first component is a matrix with columns representing the

MAP estimates of the parameters for different q\_1's, i.e., q\_1, q\_1+1, ..., max\_order. The other components are minus the curvature matrices for different q\_1's, i.e., q\_1, q\_1+1, ..., max\_order. Therefore, the first non-NA curvature matrix is equal to the output argument A\_hat. This output argument, theta\_A\_poly, is only shown if family = "survival" and basehaz = "poly", and will be used

in the function bfi();

lev\_no\_ref\_zer a vector containing the names of the levels of the categorical covariate that has

no samples/observations in one of its categories. The name of the category with no samples and the name of the reference category are excluded from this vector. This argument is shown when family = "survival" and basehaz = "poly",

and will be used in the function bfi();

zero\_sample\_cov

the categorical covariate that has no samples/observations in one of its cate-

gories. It is shown when center\_zero\_sample = TRUE, and can be used in the

function bfi();

refer\_cat the reference category. It is shown when center\_zero\_sample = TRUE, and can

be used in the function bfi();

zero\_cat the category with no samples/observations. It is shown when center\_zero\_sample

= TRUE, and can be used in the function bfi();

value the value of minus the log-likelihood posterior density evaluated at theta\_hat;

family the family used;

basehaz the baseline hazard function used;

intercept logical flag used to fit an intercept if TRUE, or set to zero if FALSE;

convergence an integer value used to encode the warnings and the errors related to the algo-

rithm used to fit the model. The values returned are:

**0** algorithm has converged;

1 maximum number of iterations ('maxit') has been reached;

2 Warning from the 'L-BFGS-B' method. See the message after this value;

control the list of control parameters used to compute the MAP estimates.

28 n.par

n.par The Number of Predictors, Coefficients, and Observations
--

## Description

n.par returns the number of regression parameters, covariates and observations present in X based on the selected family.

## Usage

```
n.par(X, family = c("gaussian", "binomial", "survival"))
```

## **Arguments**

X design matrix of dimension  $n \times p$ , where n is the number of samples observed,

and p is the number of predictors/covariables. It could be a matrix or a list of

matrices.

family a description of the error distribution used to specify the model. This should

be a character string, either "gaussian", "binomial", or "survival". Can be

abbreviated. By default the gaussian family is used.

## Details

orig.names and covar.names are the same if the all covariates in X are continuous. However, if there are at least one categorical variable in X with more than two categories, they are different.

## Value

n.par returns a list containing the following components:

n.reg.par the number of regression parameters;

n.covar the number of covariates;

n. sample the number of samples/observations;

orig. names the original names of the variables (without including the names of dummy vari-

ables);

covar.names the names of the variables (together with the names of any dummy variables, if

applicable).

Nurses

Nurses' stress in different hospitals

#### **Description**

This dataset comprises three-level simulated data extracted for a hypothetical study investigating stress levels within hospital settings. The dataset focuses on nurses working in specific wards within various hospitals. It includes several variables, such as nurse age (measured in years), nurse experience (measured in years), nurse gender (0 for male, 1 for female), ward type (0 for general care, 1 for special care), and hospital size (0 for small, 1 for medium, 2 for large). The dataset in the package is obtained from the original dataset by leaving out some of the unused columns.

#### Usage

```
data(Nurses)
```

30 summary.bfi

summary.bfi	Summarizing BFI Fits

#### **Description**

Summary method for an object with class 'bfi' created by the MAP.estimation and bfi functions.

## Usage

## Arguments

object fitted bfi object.

cur\_mat logical; if TRUE, minus the curvature matrix around the estimated parameters is returned and printed. Default is FALSE.

digits significant digits in printout.

... additional arguments affecting the summary produced.

#### **Details**

summary.bfi() gives information about the MAP estimates of parameters of the model. It can be used for the bfi objects built by the MAP.estimation and bfi functions.

The output of the summary method shows the details of the model, i.e. formula, family and link function used to specify the generalized linear model, followed by information about the estimates, standard deviations and credible intervals. Information about the log-likelihood posterior and convergence status are also provided.

By default, summary.bfi function does not return (minus) the curvature matrix, but the user can use cur\_mat = TRUE to print it.

## Value

summary.bfi returns an object of class summary.bfi, a list with the following components:

theta_hat	the component from object. The last element of this vector is the estimate of the dispersion parameter (sigma2) if family = "gaussian". See the MAP.estimation and bfi functions.
A_hat	the component from object. See the MAP.estimation and bfi functions.
sd	the component from object. If family = "gaussian", the last element of this vector is the square root of the estimated dispersion. See the MAP.estimation and bfi functions.

summary.bfi 31

Lambda	the component from object. See the MAP.estimation function.
formula	the component from object. See the MAP.estimation function.
n	the component from object. See the MAP.estimation function.
np	the component from object. See the MAP.estimation function.
family	the component from object. See the MAP.estimation function.
intercept	the component from object. See the MAP.estimation function.
convergence	the component from object. See the MAP.estimation function.
control	the component from object. See the MAP.estimation function.
stratified	the component from object. See the bfi function.
estimate	the estimated regression coefficients, i.e., without the estimate sigma2.
logLikPost	the value of the log-likelihood posterior density evaluated at estimates (theta_hat).
link	the link function only for GLMs, not for the survival family. By default the gaussian family with identity link function and the binomial family with logit link function are used.
dispersion	the estimated variance of the random error, i.e., sigma2. The dispersion is taken as 1 for the binomial family.
CI	a 95% credible interval of the MAP estimates of the parameters.

surv.simulate

Generate survival data with predefined censoring rates for proportional hazards models

## **Description**

surv.simulate simulates one or multiple (right-censored) survival datasets for proportional hazards models by simultaneously incorporating a baseline hazard function from three different survival distributions (exponential, Weibull and Gompertz), a random censoring time generated from a uniform distribution with an known/unknown upper limit, and a set of baseline covariates. When the upper limit of the uniform censoring time distribution is unknown, surv.simulate can be used separately to obtain the upper limit with a predefined censoring rate.

#### Usage

## **Arguments**

L the number of datasets to be generated. Default is L = 1.

Z a list of L design matrices of dimension  $n_{\ell} \times p$ , where  $n_{\ell}$  is the number of samples observed for the  $\ell^{\text{th}}$  dataset and p is the number of covariables. When L

= 1, Z can be a matrix.

the vector of the (true) coefficients values, with a length of p (the number of covariates).

beta

а	scale parameter, which should be non-negative. See 'Details' for the form of the cumulative hazard that can be used.
b	shape/location parameter, which should be non-negative. It is not used when gen_data_from = "exp". See 'Details' for the form of the cumulative hazard that can be used.
u1	a known non-negative lower limit of the uniform distribution for generating random censoring time. Default is $u1 = 0$ . If cen_rate is not equal to 0, then $u1$ does not need to be defined.
u2	an non-negative upper limit of the uniform random censoring time distribution. The upper limit can be unknown (u2 = NULL, the default), or predefined. When this argument is assumed to be unknown, u2 = NULL, it is calculated by the algorithm within surv.simulate(). However, if the argument u2 is known, the censoring rate cannot be predefined (meaning there is no control over it) and is calculated based on the generated dataset. See 'Details' and 'References'.
cen_rate	a value representing the proportion of observations in the simulated survival data that are censored. The range of this argument is from 0 to 1. When the upper limit is known, cen_rate can nor be predefined. If there is no censoring (cen_rate = $0$ ), the lower (u1) and upper (u2) limits of the uniform distribution do not need to be specified.
gen_data_from	a description of the distribution from which the time to event is generated. This is a character string and can be exponential ("exp"), Weibull ("weibul"), or Gompertz ("gomp"). Can be abbreviated. By default, the exponential distribution is used.
only_u2	logical flag for calculating only the upper limit of the uniform censoring time distribution. If $only_u2 = TRUE$ , the dataset(s) are not generated. If $only_u2 = TRUE$ , the arguments Z and u2 do not need to be specified, and cen_rate should not be set to 0. Default is $only_u2 = FALSE$ .
n.rep	a scalar specifying the number of iterations. This argument is exclusively used in the case of the Gompertz distribution. Default is 100.
Trace	logical flag indicating whether the output of the desired u2 and the censoring proportion for different datasets should be produced for each iteration. It works gen_data_from = "gomp".

## **Details**

surv.simulate function generates L simulated right-censored survival datasets from exponential, Weibull, or Gompertz distributions, incorporating the covariates, Z, distributed according to a multivariate normal distribution, with censoring time generated from a uniform distribution Uniform(u1, u2), where u1 is known but u2 can be either known or unknown.

surv.simulate() can also be used to calculate the unknown upper limit of the uniform distribution, u2, with a predefined censoring rate. To do this, set u2 = NULL and only\_u2 = TRUE. In this case, the datasets are not generated; only u2 is.

surv.simulate() uses a root-finding algorithm to select the censoring parameter that achieves predefined censoring rates in the simulated survival data.

When gen\_data\_from = "exp":

- the cumulative baseline hazard function is considered as  $\Lambda_0=at$ ,
- the event time for the  $\ell^{\text{th}}$  dataset,  $T_{\ell}$ , is computed by  $-log(u) \exp(-Z_{\ell}\beta)/a$ , where u follows a standard uniform distribution;

For gen\_data\_from = "weibul":

- the cumulative hazard function is as  $\Lambda_0 = at^b$ ,
- the event time is computed by  $T_{\ell} = (-log(u) \exp(-Z_{\ell}\beta)/a)^{1/b}$ , where u follows a standard uniform distribution;

For gen\_data\_from = "gomp":

- the cumulative hazard function is as  $\Lambda_0 = a(exp(bt) 1)/b$ ,
- the event time is computed by  $T_{\ell} = \log(1 \log(u) \exp(-Z_{\ell}\beta)b/a)/b$ , where u follows a standard uniform distribution;

Finally the survival time is obtained by  $\tilde{T}_{\ell} = \min\{T_{\ell}, C_{\ell}\}.$ 

The function will be updated for gen\_data\_from = "gomp".

#### Value

surv. simulate returns a list containing the following components:

D	a list of $L$ data frames, with dimension $n_\ell \times (p+2)$ . The first and second columns, named time and status, contain the simulated survival time and the censoring indicator, respectively, where $0$ means censored and $1$ means uncensored;
censor_propor	the vector of censoring proportions in the simulated datasets $\ensuremath{D}$ , containing $L$ elements;
u1	the lower limit of the uniform distribution used to generate random censoring times with a predefined censoring rate. Sometimes this output is less than the value entered by the user, as it is adjusted to achieve the desired amount of censoring rate;
u2	the upper limit of the uniform distribution used to generate random censoring times. If $u2 = NULL$ , this output will be the estimated upper limit necessary to achieve the desired censoring rate across the $L$ datasets.

```

36 trauma

trauma

Trauma patients from different hospitals

## **Description**

This data set consists of data of 371 trauma patients from three hospitals. The binary variable mortality is used as an outcome, and variables age, sex, the Injury Severity Score (ISS, ranging from 1 (low) to 75 (high)) and the Glasgow Coma Scale (GCS, which expresses the level of consciousness, ranging from 3 (low) to 15 (high)) are used as covariates. There are three types of hospitals: peripheral hospital without a neuro-surgical unit (Status = 1), peripheral hospital with a neuro-surgical unit (Status = 2), and academic medical center (Status = 3). Originally, the data come from a multi center study collected with a different aim. For educational purposes minor changes have been made, see the references below.

## Usage

data(trauma)
